

Tradeoffs between Quantum Memory and Communication

Hartmut Klauck
University of Calgary

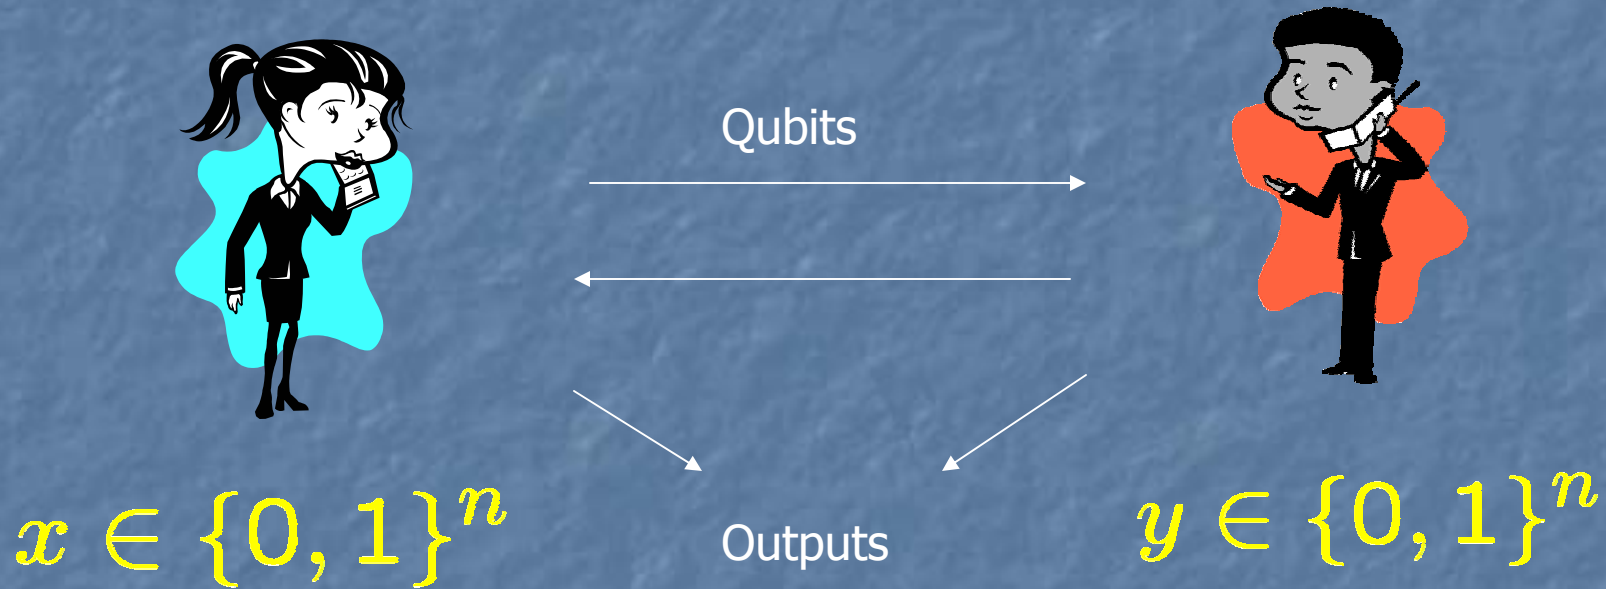

I.

Communication complexity with bounded memory

Motivation: What is the computational power of quantum computation with a limited number of qubits?

Model A): Quantum communication complexity

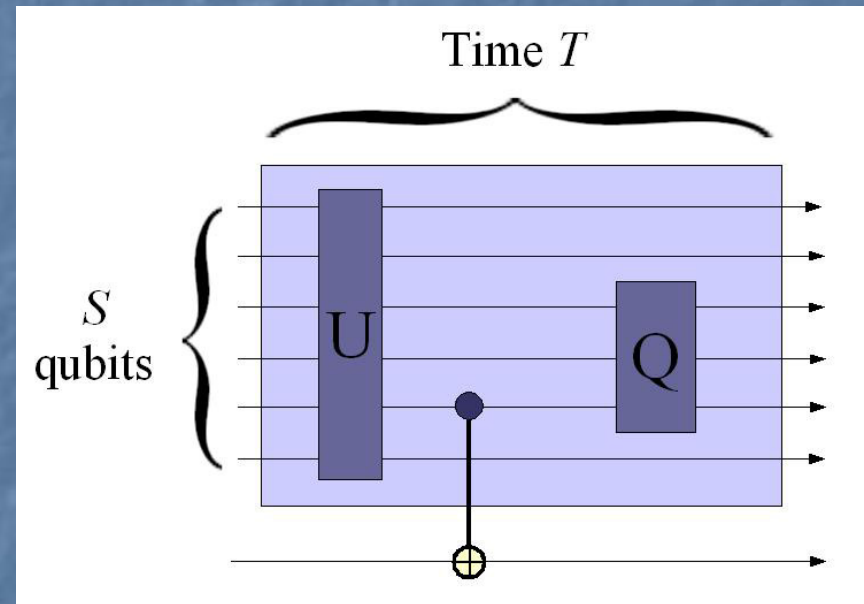

Cost of a protocol: number of qubits sent
Complexity $Q(f)$: cost of best protocol

Model B): Memory bounded quantum circuits

- Circuits on S qubits, accessing input as oracle
- U : unitary op
- output gate: *controlled not* to extra qubit
- Q : query gate:

$$|i\rangle|a\rangle \mapsto |i\rangle|a \oplus q(i)\rangle$$

Model C): Communicating quantum circuits, bounded memory

- Quantum circuit in two parts
- Separate input oracles
- Circuit with C qubit wires crossing uses communication C
- Work on S qubits

Conventions

- Outputs are sent to the other circuit
- Circuits may “drop” qubits and use fresh qubits

An Example

- $\text{DISJ}(x,y)=1$ iff $\sum_{i=1..n} x_i \wedge y_i > 0$
- Grover-like Protocol [BCW98] searches for i with $x_i=y_i=1$
- Uses $O(\log n)$ qubits and $O(n^{1/2} \log n)$ communication
- No classical protocol is better than $\Omega(n)$ [KS87] (independent of space)
 $O(n)$ with space $O(\log n)$ possible
- So does more memory ever help?

Functions

- Let $f: \{0,1\}^n \times \{0,1\}^n \rightarrow \{0,1\}$
- Then $f_{l,r}$ computes on $\{0,1\}^n \times \{0,1\}^n$
 $f(x,y)$ for all $l \neq r$ pairs of inputs (l outputs)

Functions

- Examples:
- $IP(x,y) = \bigodot_{i=1..n} x_i \text{ \&E } y_i$ (inner product)
- $DISJ(x,y) = 1$ iff $\sum_{i=1..n} x_i \text{ \&E } y_i > 0$

- $DISJ_{n,n}$ Boolean matrix product
- $IP_{n,n}$ Matrix product GF(2)
- $IP_{n,1}$ Matrix vector product

Complexity Notation

- Always allow error $1/3$
- $C_S(f)$ denotes classical communication with space S
- $Q_S(f)$ denotes quantum communication with space S

Results

- Inner Product:

$$C_S(\text{IP}_{l,r}) < O(l r n / \min\{S, l\})$$

$$Q_S(\text{IP}_{l,r}) > \Omega(l r n / S)$$

$$C_S(\text{IP}_{n,n}) = \Theta(n^3/S) = \Theta(Q_S(\text{IP}_{n,n}))$$

$$C_S(\text{IP}_{n,1}) = \Theta(n^2/S) = \Theta(Q_S(\text{IP}_{n,1}))$$

Results

- More general, f with discrepancy bound d have $Q_S(f_{l,r}) > \Omega(l r d / S)$.
- Classically: Beame et al. prove lower bounds for universal hash functions

What about DISJ?

- Disjointness:

$$Q_S(\text{DISJ}_{l,r}) < \tilde{O}(l r n^{1/2} / S^{1/2})$$

$$Q_S(\text{DISJ}_{n,n}) < \tilde{O}(n^{2.5} / S^{1/2})$$

$$Q_S(\text{DISJ}_{n,1}) < \tilde{O}(n^{1.5} / S^{1/2})$$

- Even classical lower bound for $\text{DISJ}_{n,n}$ unknown!, probably $\Theta(n^3 / S)$

II.

Inner product modulo 2

Inner product, upper bound

- Assume $l, r > S$
- Solve $IP_{S,1}$ and iterate $l/S \notin r$ times
- To solve $IP_{S,1}$ Bob sends S bits of his input, Alice computes partial sums for all S function values
- Iterate n/S times
- Overall complexity $l/S \notin r \notin S \notin n/S = l r n / S$
- Storage S

Inner product, upper bound

Compute $\sum_{i=1..S} x_i^{(j)} \wedge y_i$ for all $j=1..S$

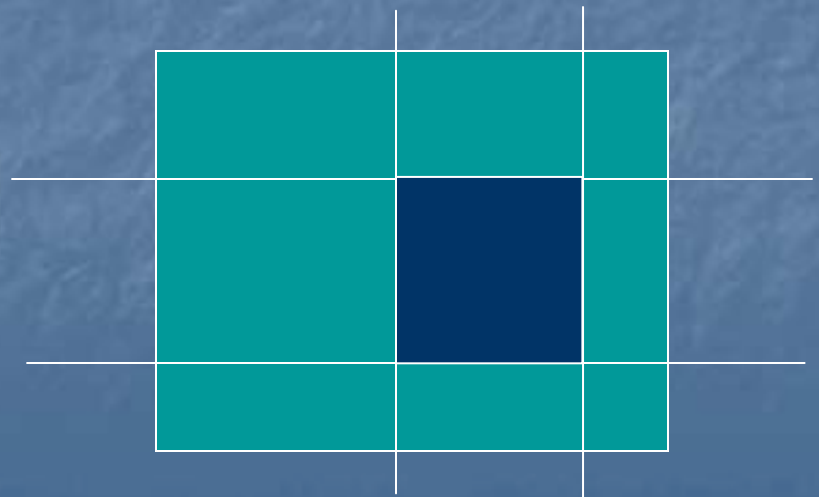

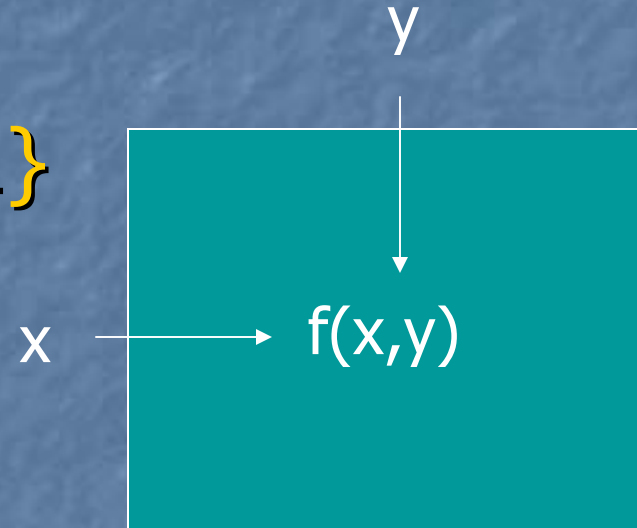

Compute $\sum_{i=1..2S} x_i^{(j)} \wedge y_i$ for all $j=1..S$

etc.

The lower bound

- $f: \{0,1\}^n \times \{0,1\}^n \rightarrow \{0,1\}$
- M_f is the communication matrix:

- **Rectangle**: product set in the matrix

The discrepancy bound

- $\text{disc}(f) = \max_R |\mu(R \cap f^{-1}(1)) - \mu(R \cap f^{-1}(0))|$
over rectangles R (uniform distribution μ)
- [KY]: $Q(f) > \Omega(-\log \text{disc}(f))$
- Here: $Q_S(f_{l,r}) > \Omega(\ln \phi - \log(\text{disc}(f))/S)$

Application

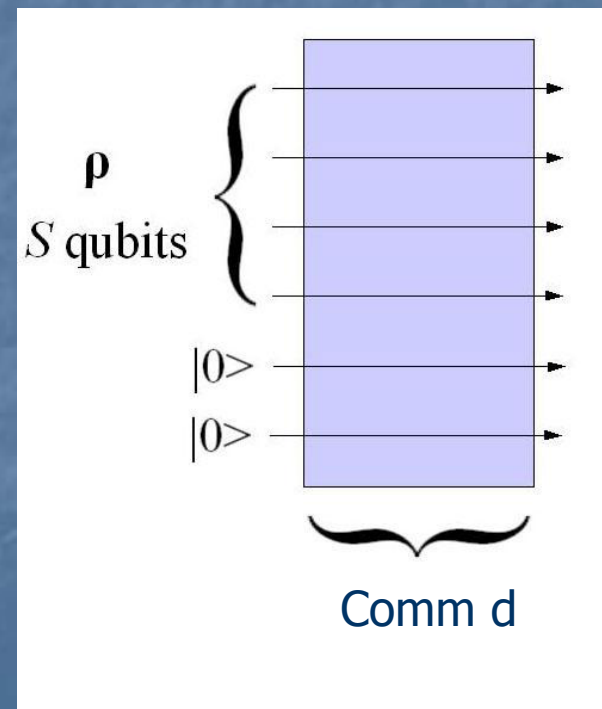

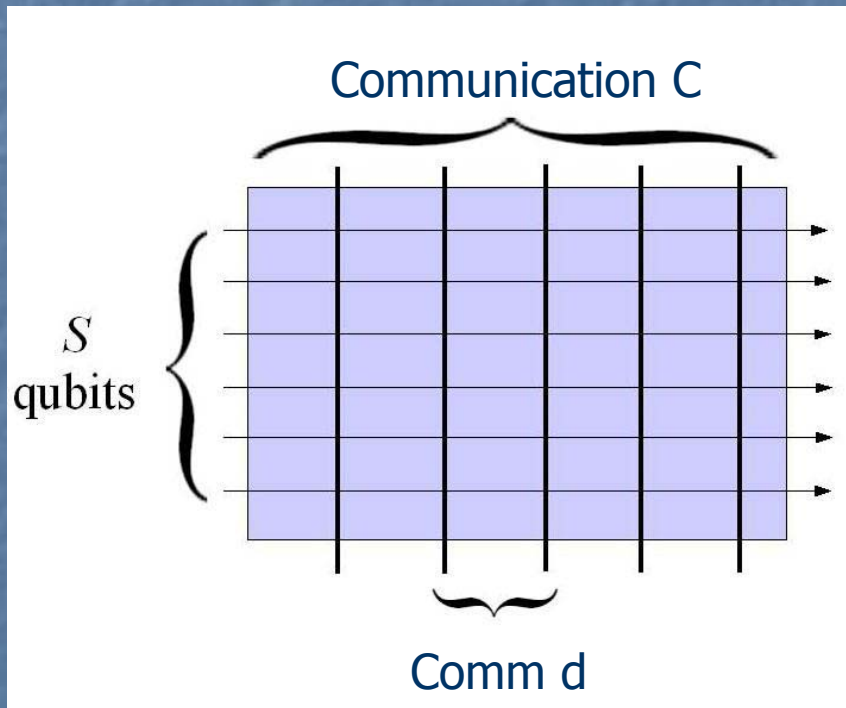

- [Chor et al.] $\text{disc}(\text{IP}) < 1/2^{n/2}$
- Hence $Q_S(\text{IP}_{l,r}) > \Omega(\ln n/S)$
- Matrix Product over GF(2) needs communication n^3/S ,
Matrix Vector Product needs n^2/S

How to prove it

- Given circuit pair with communication C and space S
- Slice the circuit into segments containing communication d , if $\text{disc}(f) \geq \frac{1}{4} \frac{1}{2^d}$
- Intuitively not enough communication to compute f even once
- Show that each slice can make few outputs, namely $O(S)$
- Then $C/d \geq S > \Omega(\log r)$

Slicing the circuit

Show: $\ll O(S)$ outputs

How to prove it

- If each slice has $O(S)$ outputs, then:
 $C/d \notin O(S) > lr$
- Furthermore can assume that $S < o(d)$,
since else with $C > lr$ we get $C > \Omega(lr d/S)$

The initial information

- Suppose a circuit produces some output with probability p , given some initial state ρ on S qubits.
- Idea: replace ρ by the totally mixed state.
- Claim: circuit succeeds with probability $p/2^S$
- Reason: every quantum state “sits” in the totally mixed state with “size” $1/2^S$

Why that?

- Totally mixed state is
 $M = \text{diag}(1/2^S, \dots, 1/2^S)$
- For all density matrices ρ there is a density matrix σ so that
 $M = 1/2^S \rho + (1 - 1/2^S) \sigma$

Direct Products

- Given communicating quantum circuits with communication d
- Produce L outputs with success probability $\frac{2}{3} \not\leq \frac{1}{2^S}$.
- Show that all such circuits have success probability at most $\frac{1}{2^{\Omega(L)}}$
- Then $L=O(S)$
- Need to show this only for $L < o(d)$

Direct Products

- $f_{l,r}$ with $\text{disc}(f) < 1/2^d$.
- Select $L = \text{const} \ll S = o(d)$ and $L < lr$ and L outputs for $f(x_i, y_j)$
- Show that success probability of a quantum protocol w/ communication d is $1/2^{\Omega(L)}$
- Hardest case: $L = lr$ (most dependencies)

Direct Products

- Know that each rectangle in $\{0,1\}^n \times \{0,1\}^n$ contains $\frac{1}{2} \pm \frac{1}{2^d}$ zero-inputs and $\frac{1}{2} \pm \frac{1}{2^d}$ one-inputs or has size $< \frac{1}{2^d}$
- A) Show that rectangles in $\{0,1\}^{n_1} \times \{0,1\}^{n_2}$ contain each of $L=2^{lr}$ function values with probability $\frac{1}{2^L} \pm \frac{1}{2^{d/2}}$ for $L < o(d)$
- B) Show that each quantum protocol with communication d and correctness $2^{-o(L)}$ induces better rectangles

A)

- Rectangle in $\{0,1\}^{nr} \times \{0,1\}^{nr}$
- What is probability of $f(x_i, y_i) = c_{ij}$ for all i, j and some fixed c_{ij} ?

Product of conditional probabilities that $f(x_i, y_j) = c_{ij}$ given previous $f(x_u, y_v) = c_{uv}$.

A)

- Current input pair: x_i, y_j
- Conditions not involving x_i or y_j , white
- Conditions involving x_i or y_j , red

A)

- Fix all x_u, y_v other than x_i, y_j
- Obtain rectangle R in $\{0,1\}^n \times \{0,1\}^n$
- Case 1: R is smaller than $1/2^d$
All such rectangles can have combined size $1/2^d$ at most
(in uniform distribution on $\{0,1\}^n \times \{0,1\}^m$)

A)

- Other case: R is "large"
- Further conditions: $f(x_i, y_v) = c_{iv}$
(row conditions)
- $f(x_u, y_j) = c_{uj}$ (column conditions)
- Lead to $< 2^L$ disjoint subrectangles
- Each contains $1/2^L \times 1/2^d$ zeroes/ones
- Overall R contains $1/2^L \times 2^L/2^d$ zeroes/ones

A) fin.

- Hence

$$\text{Prob}(f(x_i, y_j) = c_{ij}) < 1/2 + 2^L/2^d < 1/2 + 2^{d/2}$$

for all conditions

- $\text{Prob}(f(x_i, y_j) = c_{ij} \text{ for all } i, j)$
< $(1/2 + 1/2^{d/2})^L$
< $1/2^L + 2/2^{d/2}$

B)

- Given is a quantum protocol with L outputs, communication C and success probability $1/2^L + p$
- Find a rectangle that contains inputs with $f(x_i, y_j) = c_{ij}$ in proportion $1/2^L + p/2^C$
- Proof by decomposing protocols into weighted rectangles

II.

Disjointness

Disjointness upper bound

- $\text{DISJ}(x,y)=1$ iff $\sum_{i=1..n} x_i \wedge y_i > 0$

- $Q_S(\text{DISJ}_{l,r}) < \tilde{O}(l r n^{1/2} / S^{1/2})$

$$Q_S(\text{DISJ}_{n,n}) < \tilde{O}(n^{2.5} / S^{1/2})$$

$$Q_S(\text{DISJ}_{n,1}) < \tilde{O}(n^{1.5} / S^{1/2})$$

Upper bound

- Solve $\text{DISJ}_{S,1}$ with communication $\tilde{O}((nS)^{1/2})$ and space S
- Iterate $\ell r/S$ times, communication $\tilde{O}(\ell r/S \cdot (nS)^{1/2}) = \tilde{O}(\ell r n^{1/2}/S^{1/2})$

Protocol for $\text{DISJ}_{S,1}$

- Alice has sets x_1, \dots, x_S ; Bob has set y
- Alice and Bob run a Grover-like protocol on $z = [x_i \text{ and } y$
- Find $j \in z \cap y$
- Determine all x_i with $j \in x_i$, call their union z'
- Set $z = z - z'$ and iterate.

Protocol

- **Problem:** cannot store z explicitly (size n)
- Can store array of inputs x_i for which output is already computed
- Construct superposition $\sum_{j:j^2=z} |j\rangle$ from oracle and array
- During the protocol use the oracle to implement each Grover iteration

Analysis

- Assume that $|z \wedge y| = K_1$ in step 1.
- Then one element in the intersection can be found with $\tilde{O}(n^{1/2} / K_1^{1/2})$ Grover iterations
- All elements can be found with $\tilde{O}(n^{1/2} \cdot K_1^{1/2})$ iterations
- If $K_1 < S$ then find all with $(nS)^{1/2}$ at most
- If $K_1 > S$, then find one element with $n^{1/2} / S^{1/2}$ at most, at most S iterations
- Cost always $(nS)^{1/2}$

Conclusion

- Have analyzed the effect of a limited number of qubits on the quantum communication complexity
- If the discrepancy bound is good, then quantum does not seem to help
- Matrix product over $GF(2)$: no speedup by quantum
- For Boolean matrix vector product: given upper bound

Open Problems

- Lower bounds for $\text{DISJ}_{l,r}$, i.e., for Boolean matrix products (even open classically)
- Communication-space tradeoffs for decision problems
